## ABSTRACT

The emerging conversion-type chalcogenide anode materials for potassium ion storage may propose high theoretical specific capacity ( $>600 \text{ mA h g}^{-1}$ ) and high compatibility with electrolytes, but currently the reported performance falls behind this goal due to severe material pulverization, polysulfide shuttle effect, and slow potassium ion diffusion during a charge/discharge process. Here, we report that Cu<sub>3</sub>PS<sub>4</sub>, a sulfur-rich orthorhombic metal phosphosulfide, can achieve highly reversible multiple conversion reactions, including the formation of KP and K<sub>2</sub>S along with 9 electrons transfer and efficient diffusion of potassium ions. Moreover, we introduce a layer graphite surface coating to enhance the overall conductivity of the electrodes, decrease the internal resistance, and render specific electronic channel with fast kinetic diffusion. During cycling, a tightly connected K-Cu-P-S junctions were formed to establish an ultra-stable heterostructure to entrap polysulfides in materials via an appropriate and uniform affinity. In electrochemical tests, Cu<sub>3</sub>PS<sub>4</sub> potassium ion anodes exhibit the highest capacity of  $649.3 \text{ mA h g}^{-1}$  at a current density of  $0.05 \text{ A/g}$ , reaching 94.4 % of its theoretical capacity ( $687.3 \text{ mA h g}^{-1}$ ), and showed an ultra-stable 3000 cycle life and high-rate capability up to  $8 \text{ A/g}$ . Furthermore, the full battery and hybrid capacitor show attractive energy density and long cycle life of  $82.5 \text{ W h kg}^{-1}$  for 800 cycles and  $80.3 \text{ W h kg}^{-1}$  for 5000 cycles, respectively. This work provides promising results for metal phosphosulfide applications in high-efficiency potassium-ion storage devices, and may also be instructive for material advancements in related energy fields.

## 1. Introduction

Lithium-ion batteries with long cycle life [1–3] and high-power density [4–7] have breakthrough applications in electrified transportation and portable electronics [8]; however, the insufficient lithium content in the earth's crust and the high cost of lithium metal remain a challenge for widespread applications in the future [9–11]. In this scenario, potassium-ion batteries have become the alkali metal analogs of electronic conversion technology in recent years due to their similar physical and chemical properties to lithium-ion batteries [12]. Their low cost ascribed to the abundant resources (1.5 wt%), and the standard redox potential of K<sup>+</sup>/K (−2.93 V) is higher than that of Li<sup>+</sup>/Li (−3.04 V), enabling its application to work at high operating voltages and higher energy density in full cells [13–17]. In addition, the similar intercalation chemistry endows potassium-ion batteries with chemical reactions at high potential [18–20]. On the other hand, low-cost aluminum foil can be used as a current collector, so that the weak Lewis acidity of potassium ions enhances their diffusion in various electrolyte [21,22], and

effectively relieves the polarization at the interface between the electrolyte and the electrode [23–26]. Nonetheless, the large atomic radius of potassium ions makes it difficult to intercalate into electrode materials, resulting in less specific capacity and accompanying poor kinetic response and rate performance [27,28].

Transition metal sulfides which possess high theoretical volume capacity, intrinsic conductivity and ionic conductivity have received great attention in recent years [29–36], such as SnS<sub>x</sub> [37,38], CuS<sub>x</sub> [39], MoS<sub>x</sub> [40], TiS<sub>x</sub> [41] and so on. Since the M–S bond between MS<sub>x</sub> is weaker than the M–O bond, and the final conversion product M<sub>2</sub>S<sub>x</sub> produced by MS<sub>x</sub> during the charge–discharge reaction is more conductive than M<sub>2</sub>O, metal sulfides with better kinetic properties are more suitable for potassium ion battery systems than metal oxides [42,43]. However, direct use of these materials exhibits poor cycling performance due to ineffective activation. Carbonaceous materials are widely used to the form a layer structure on the electrode surface, thereby simultaneously improves the overall conductivity of the electrode [44–47]. Together with the increase of active sites in the electrolyte, the active material can

transport potassium ions more efficiently during cycling, which further improves the rate performance [48]. Nevertheless, transition metal sulfides often face the redox shuttle effect during the charge–discharge process, resulting in the formation of polysulfides that repeatedly dissolve in the electrolyte, leading to continuous loss of active materials during chemical reactions. Although carbon-coated materials can effectively suppress the collapse of the structure, the non-polar carbon framework is difficult to dissolve polysulfides through physical adsorption. It has been pointed out that physical adsorption and chemical bonding of polysulfides are the most commonly applied solutions, but doping other host materials may increase the overall active material weight and reduce the volumetric capacity of the electrode at the same time [49,50]. Among binary transition metal sulfides, few anode materials can effectively alleviate the polysulfide dissolution problem, resulting in mediocre performance in full-cell applications or potassium-ion hybrid capacitors (PIHCs). To this situation, several recent studies have proved that the polyatomic synergistic effect induced via the addition of metal elements can increase the contact area between the active material and the electrolyte [51,52], and shorten the diffusion distance of metal ions. Compared with monometallic sulfides, the addition of elements such as phosphorus, antimony, bismuth and some VA group element may boost the synergistic effect and can provide more redox active centers [53,54], and render fast electronic conduction.

Ternary transition metal sulfides are intrinsic variants of binary transition metal sulfides with high electrical conductivity and more redox active sites relative to metal oxides and metal hydroxides. Ternary sulfides with 3d orbitals may enable the existence of many Lewis acids and bases between polar materials and polysulfides, so that the migration of polysulfides is greatly restricted by chemical bonds. Compared with polar oxides, polar sulfides have higher electronic conductivity, so they may be more suitable as sulfur frameworks, which can also effectively adsorb polysulfides. For example, Kim *et al.*, applied the ternary transition metal sulfide  $\text{NiTi}_2\text{S}_4$  to Li-ion batteries and found that insoluble  $\text{Li}_2\text{S}$  is formed during the intercalation/de-lithiation reaction instead of LiPSs [55]. Guo *et al.* found that the ternary transition metal sulfide (FCN111) has surface electro-positivity, and its strong Lewis acid-base interaction can further avoid the formation of LiPSs [56]. Yan *et al.* found that the ternary material  $\text{MnCo}_2\text{S}_4$  synthesized by sulfuration can utilize its unique crystal structure to prevent the electrode powder agglomeration, thereby inhibiting the shuttle effect [57]. Based on the above viewpoints, the effective combination of ternary transition metal sulfide and carbon layer can simultaneously stabilize the electrode and overcome the redox shuttle effect, prolonging anode life span and rate performance of the electrode.

In this study, an orthorhombic ternary metal phosphosulfide  $\text{Cu}_3\text{PS}_4/\text{G}$  were prepared by high-energy ball milling with a specific molar ratio of copper, phosphorus, and sulfur as precursors, and graphite. By enhancing the synergistic effect of elements of the ternary materials to improve the diffusivity of potassium ions, and through simulation and experimental mutual corroboration, the advantages of  $\text{Cu}_3\text{PS}_4/\text{G}$  compared with  $\text{CuS}/\text{G}$  were confirmed and the challenges such as the shuttle effect and long-term cycling performance of metal sulfides were resolved. The theoretical calculation shows that potassium ions have a low-energy barrier in the material to effectively capture potassium polysulfides through the synergistic effect of ternary materials during conversion reaction. In addition,  $\text{Cu}_3\text{PS}_4/\text{G}$  can also reach the highest specific capacity  $649.3 \text{ mA h g}^{-1}$  at  $50 \text{ mA g}^{-1}$  as well as the high electrochemical performance in other aspects, including capacity retention (CR), initial Coulombic efficiency (ICE), long term cycle number, and high current density. Finally, we fabricated a full battery with Prussian blue ( $\text{K}_x\text{Fe}(\text{Fe}(\text{CN}_6))$ ) and a hybrid capacitor using activated carbon as a cathode, respectively. Both showed attractive energy density and long cycle life, which are  $82.5 \text{ W h kg}^{-1}$  at 800 cycles for batteries and  $80.3 \text{ W h kg}^{-1}$  at 5000 cycles for hybrid capacitor, respectively.

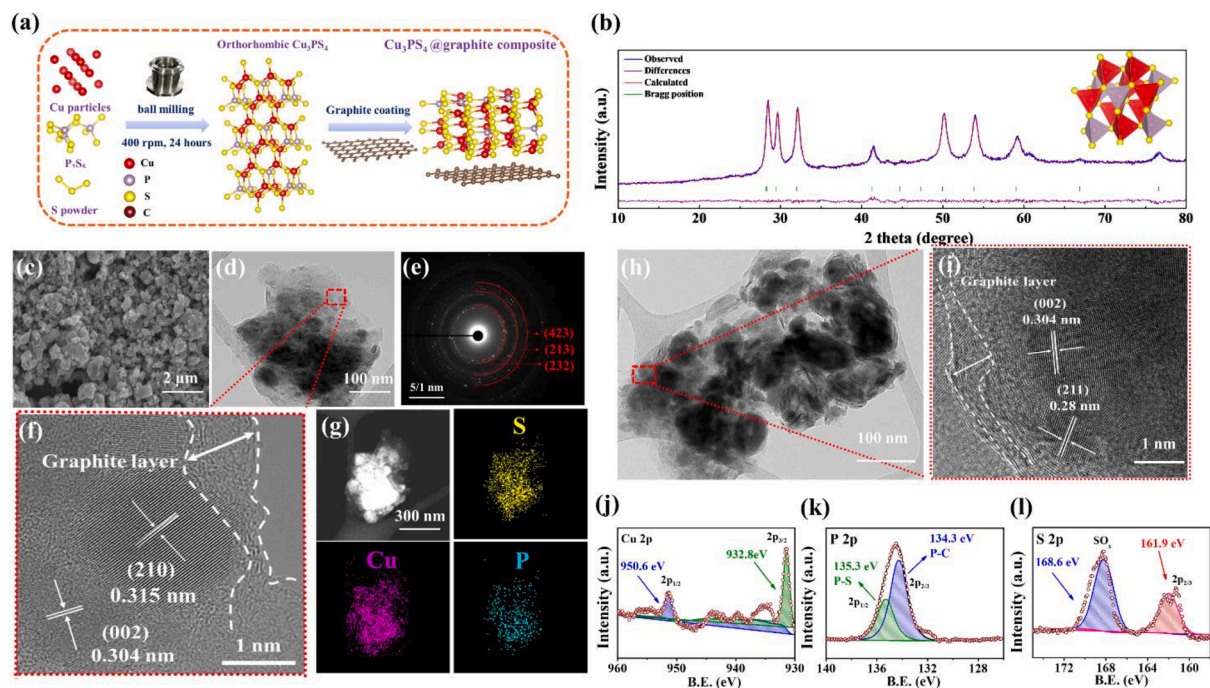

## 2. Results and discussion

### 2.1. Material characterization

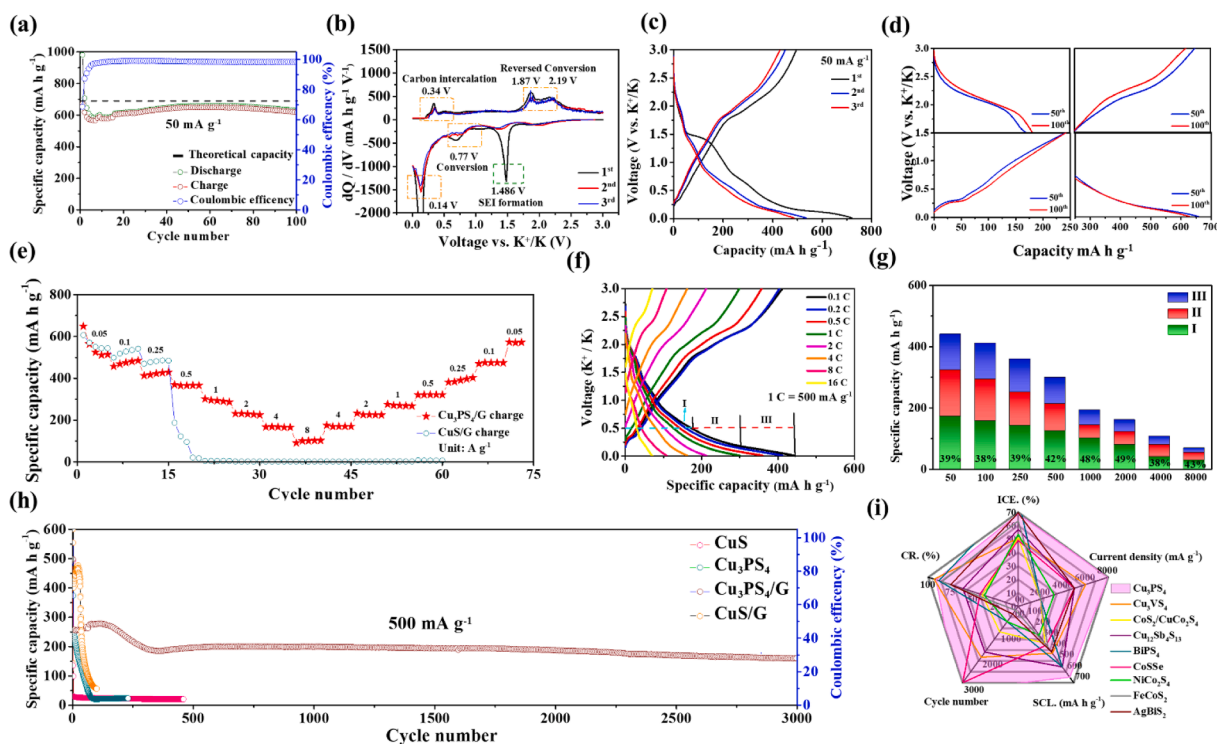

The schematic illustration of the synthesis of pristine  $\text{Cu}_3\text{PS}_4$  nanoparticles by high-energy ball milling was shown (Fig. 1a). We performed a two-step high-speed ball milling, firstly, Cu particles,  $\text{P}_2\text{S}_5$ , and sulfur powders were mixed in a zirconia jar with a stoichiometrically molar ratio of 6:1:3, the first ball milling is carried out in the state without oxygen, and the elements are forced to bond with extremely high energy. The second step ball milling not only coats the graphite evenly on the periphery of pristine  $\text{Cu}_3\text{PS}_4$ , but also grind the powder finely at high rotational speed so that it can be applied to the electrode material. The crystal structure of the as-synthesized pristine  $\text{Cu}_3\text{PS}_4$  was analyzed by XRD (Fig. 1b), showing all the diffraction peaks of pristine  $\text{Cu}_3\text{PS}_4$  consistent with the Rietveld refined results corresponding to the  $Pmn21$  [31] space group, indexed to an orthorhombic crystal system. Given the fitting curves, no other peaks were observed except for the index, and the obtained lattice parameter of  $\text{Cu}_3\text{PS}_4$  is identical to the theoretical value. Furthermore, the XRD pattern of  $\text{Cu}_3\text{PS}_4/\text{G}$  are shown (Fig. S1b). It is clear that  $\text{Cu}_3\text{PS}_4/\text{G}$  coated with layered graphite shows an obvious peak of graphite at the position where the 2 theta is  $20.8^\circ$ , indicating that the graphite and pristine  $\text{Cu}_3\text{PS}_4$  form a uniform composite. The morphology of the as-prepared  $\text{Cu}_3\text{PS}_4/\text{G}$  is observed by scanning electron microscope (SEM) (Fig. 1c). It can be seen that the size of the nanoparticles of  $\text{Cu}_3\text{PS}_4/\text{G}$  ranges from 50 nm to 1  $\mu\text{m}$ , and due to the high energy ball milling, the nanoparticle size of  $\text{Cu}_3\text{PS}_4/\text{G}$  with a non-fixed shape and larger aggregates can be observed in the SEM images. Local analysis of  $\text{Cu}_3\text{PS}_4/\text{G}$  by transmission electron microscopy (TEM) (Fig. 1d) revealed that the outermost layered graphite uniformly covers the material, maintaining the stability of the structure by forming a uniform complex. In addition, the selected area electron diffraction (SAED) (Fig. 1e) shows three ring patterns corresponding to (232), (213), (423) crystal planes, which is consistent with the diffraction peaks of the XRD result. The high-resolution TEM image of  $\text{Cu}_3\text{PS}_4/\text{G}$  was demonstrated (Fig. 1f), indicating the d-spacing of planes (210) and (002) with a corresponding lattice spacings of 0.315 nm and 0.304 nm, respectively. The white illustrated frame elucidates the boundary where the  $\text{Cu}_3\text{PS}_4/\text{G}$  nanoparticles are uniformly covered by the graphite layer. In addition, we used X-ray energy dispersive elemental analysis (EDS) to analyze the nanoparticles captured by TEM. It can be seen that the three elements of copper, phosphorus and sulfur are uniformly distributed in the field (Fig. 1g). Among them, the signal intensities of copper and sulfur are similar, obviously more than that of phosphorus, consistent with the molar ratio of the elements contained in the  $\text{Cu}_3\text{PS}_4/\text{G}$  compound. Another area of the morphology of  $\text{Cu}_3\text{PS}_4/\text{G}$  nanocomposite (Fig. 1h) shows  $\text{Cu}_3\text{PS}_4/\text{G}$  covered by layer graphite uniformly as well. The d-spacing index demonstrates crystal plane of (002) and (211) with d-spacing of 0.304 nm and 0.28 nm, respectively (Fig. 1i). The XPS spectra were also used to qualitatively analyze the valence states of elements in  $\text{Cu}_3\text{PS}_4$ . The C orbital of  $\text{Cu}_3\text{PS}_4/\text{G}$ , and the C—C bond and C—P bond can be corresponded with the graphite coating (Fig. S3), while the peaks at binding energies 952.5 eV and 932.5 eV are mainly attributed to Cu  $2p_{1/2}$  and Cu  $2p_{3/2}$ , from Cu-P and Cu-S bonds, respectively (Fig. 1j). Furthermore, the binding energies at 134.3 eV and 135.3 eV correspond to the splitting of the P 2p core orbital, distinguished as P—C bond and P—S bond originating from the graphite and pristine  $\text{Cu}_3\text{PS}_4$  (Fig. 1k). From the result, it is evident that graphite may form a chemical bonding with pristine  $\text{Cu}_3\text{PS}_4$ , attributed to the high-energy ball milling process. In the spectrum of S 2p (Fig. 1l), characteristic peaks at 168.6 and 161.9 eV can be considered as  $\text{SO}_x$  and S  $2p_{3/2}$ .

### 2.2. Electrochemical tests and analysis

We evaluate the electrochemical performance of  $\text{Cu}_3\text{PS}_4/\text{G}$

composite by assembling a coin-type half-cell tested at voltage ranging from 0.01 V ~ 3 V. In general, the reversible specific capacity directly reflects the utilization efficiency of the conversion products, *i.e.*, KP and K<sub>2</sub>S, while the cycle life shows how the electrode suppresses the redox shuttle effect induced by the chalcogenide electrode. The galvanostatic charge–discharge curves of pure graphite is shown (Fig. S4), and the result confirms that graphite may render a reversible capacity of 107 mA h g<sup>-1</sup>, which is 38 % of its theoretical capacity. Therefore, based on the proportion of graphite to the Cu<sub>3</sub>PS<sub>4</sub>, graphite provides a capacity of approximately 30 mA h g<sup>-1</sup> to the Cu<sub>3</sub>PS<sub>4</sub>/G electrode. Therefore, layer graphite may not significantly influence the reversible capacity of Cu<sub>3</sub>PS<sub>4</sub>, but decrease the overall resistance of the electrodes during chemical reaction. Furthermore, it provides effective activation and protection to Cu<sub>3</sub>PS<sub>4</sub>, allowing a stabler charge–discharge process. In addition, the CV curves of Cu<sub>3</sub>PS<sub>4</sub>/G at the scan rate of 0.1 mV s<sup>-1</sup> is exhibited (Fig. S5). The result suggests that Cu<sub>3</sub>PS<sub>4</sub>/G electrode undergo reversible chemical reaction due to the overlap of curves. Except for the obvious difference at 1st cycle because of SEI formation, the result proves the excellent reversibility of the material. The cyclic performance of Cu<sub>3</sub>PS<sub>4</sub> /G at low current density (50 mA g<sup>-1</sup>) is demonstrated (Fig. 2a). It shows that the electrode obtains 69 % of the initial Coulombic efficiency, and delivers the highest capacity of 649.3 mA h g<sup>-1</sup> at the 60th cycle, and maintains 617.8 mA h g<sup>-1</sup> at 100 cycles. Notably, the reversible capacity reaches 94.4 % of the theoretical capacity (687.3 mA h g<sup>-1</sup>) at 60 cycles, and is still as high as 90.0 % at 100 cycles. In order to analyze how the internal chemical reaction contributes to such a high reversible capacity, we plot a dQ/dV diagram of the galvanostatic charge–discharge curves in the first three cycle (Fig. 2b). First, there is a large peak difference around 1.48 V in the first cycle, which can be attributed to the growth of the solid electrolyte interface (SEI) resulted from irreversible reaction. Furthermore, the three curves are overlapped visibly at 0.77 V, we deduced that the first conversion reaction occurred at this potential, which may be the conversion of Cu<sub>3</sub>PS<sub>4</sub>/G into K<sub>2</sub>S<sub>4</sub> and K<sub>2</sub>S<sub>3</sub>, while the peak at 0.14 V can be attributed to the formation of KP [58]. During the charging process, the plateau positions where the electricity is mainly contributed are 0.34 V, 1.87 V, and 2.19 V. Among them, 0.34 V and 1.87 V are known from the references as the intercalation of carbon and conversion reaction of phosphorus [59], and 2.19 V is the conversion reaction of sulfur, both of which are reversible reactions. Furthermore, as can be seen from the height of the curve, the electrical contribution of phosphorus is greater than that of sulfur because it has a more pronounced redox reaction. Apart from the difference in the first cycle due to unfavored side reactions, the good reversibility of the electrode is from the degree of superposition owing to the overlap of the curves. In order to show that the plateau is still obvious after many cycles, we plot the charge–discharge curves in 50th and 100th cycle and compare them with the 1st cycle (Fig. 2c). Except for the irreversible side reactions in the first cycle and the formation of the SEI film, the locations of the platforms are similar. If the specific potential interval is enlarged and viewed (Fig. 2d), the charge–discharge curves of the 50th and 100th cycles can be divided into two main platforms, corresponding to the multiple conversion reactions of S and P, respectively. The degree of superposition shows that the electrode has almost no overpotential, indicating that the charge transfer resistance (R<sub>ct</sub>) is small during the phase transition. We also tested the rate capability of the electrodes at current densities ranged from 0.05 to 8 A g<sup>-1</sup> (Fig. 2e). The reversible capacity of Cu<sub>3</sub>PS<sub>4</sub>/G are 563, 468, 416, 365, 301, 231, 167, and 90 mA h g<sup>-1</sup>, at 50, 100, 250, 500, 1000, 2000, 4000, 8000 mA g<sup>-1</sup>, respectively. After the current density is restored to 50 mA g<sup>-1</sup>, the capacity can still be maintained 570.2 mA h g<sup>-1</sup>, showing good retention after high rate. Furthermore, the pristine Cu<sub>3</sub>PS<sub>4</sub> and CuS both perform poor by applying rate capability test (Fig. S6). The charge capacity of Cu<sub>3</sub>PS<sub>4</sub> decay at 0.05 mA g<sup>-1</sup>, which shows that it cannot be fully charged and discharged even at a low current density. On the other hand, although CuS can react stably, its capacity is only 81.5, 46.6, 31.1, 18.4, 8.9, 4.7, 4.1, 2.4 mA h g<sup>-1</sup> at

0.05, 0.1, 0.25, 0.5, 1, 2, 4, 8 A g<sup>-1</sup>, respectively, and the low capacity shows that pure CuS and CuS/G cannot withstand high current densities. The charge–discharge curve of rate performance shows obvious plateau at high current density with low overpotential (Fig. 2f), indicating good reaction kinetics and stable diffusion ability of potassium ions. We divide the charge–discharge curve of rate performance into three main stages to analyze the degree of capacitance contributed by the conversion reaction respectively (Fig. 2g). The conversion reaction of phosphorus corresponded to stage I, and the conversion reaction of sulfur (K<sub>x</sub>S<sub>y</sub>) at stage II contributed the capacitance value. As for stage III, it consists of carbon intercalation and conversion reaction. The result shows that stage I provide the most percentage of capacity of about 40 %, while stage II contributes for about 30 % of the capacity. The bar further confirms that the reversible capacity is mostly contributed through the conversion reaction. As a result, we believe that more redox active sites are ionic and electronically continuous diffusion paths, contributing to the enhanced storage capacity of potassium ions and their migration in the electrode. Finally, we tested the long-term test at 0.5 A g<sup>-1</sup> (Fig. 2h), showing that Cu<sub>3</sub>PS<sub>4</sub> /G can still deliver a reversible capacity of about 180 mA h g<sup>-1</sup> with an average Coulombic efficiency of 99.97 % for over 3000 cycles. The high Coulombic efficiency is attributed to the surface treatment of the structure and the uniform contact with electrolyte [60]. On the contrary, the binary CuS and the CuS/G exhibited poor cycling performance as their reversible capacity dropped to below 60 mA h g<sup>-1</sup> after 100 cycles, with 98.55831 % of the average Coulombic efficiency at 100 cycle. In addition, CuS and the CuS/G present poor behaviors by applying different electrolyte (Fig. S7), indicating the inferior compatibility of the electrolyte and the material. The above results conclude that Cu<sub>3</sub>PS<sub>4</sub>/G has outstanding performance in both long-term cycle test and low-rate capability. As a result, we illustrate the radar chart of recent research of ternary metal sulfides in potassium-ion battery [61–68]. The electrochemical performance comparison of Cu<sub>3</sub>PS<sub>4</sub>/G and other ternary metal sulfides is demonstrated (Fig. 2i), including low-rate specific capacity (SCL), capacity retention (CR), initial Coulombic efficiency (ICE), long term cycle number, and high current density applied during rate performance test. As shown from the radar chart, this work obtained the largest area after comparing the five precise indicators. Aside from a leading performance of low-rate specific capacity, Cu<sub>3</sub>PS<sub>4</sub>/G anode exhibits a high initial Coulombic efficiency and shows its stability of rate capability at the highest current density. This result shows the appreciable electrochemical performance in many aspects among ternary metal sulfides through overcoming the redox shuttle effect and poor kinetic behavior.

### 2.3. Reaction mechanism of Cu<sub>3</sub>PS<sub>4</sub>/G

We analyze the crystal structure of the charge/discharge product at various voltages (Fig. 3a). When the electrode was discharged from the open-circuit voltage to 1.5 V, the first-step conversion reaction of Cu<sub>3</sub>PS<sub>4</sub>/G was initiated. We found that the diffraction peaks of the original material disappeared, and the peaks of KP (PDF #04-003-7018), K<sub>2</sub>S<sub>4</sub> (PDF #00-030-0992) and K<sub>2</sub>S<sub>3</sub> (PDF #04-007-0574) were located at the positions of 30.8°, 37.6°, and 54.4°, respectively, and their corresponded crystal planes were (1 1 2) and (3 3 2). As the potassium ions constantly inserted into the electrode, the voltage dropped to 0.01 V, *i.e.*, the fully-inserted state. It can be observed that the diffraction peak of KP is larger, and the phase of the first conversion reaction also disappears, confirming that KP is the final reduction product. Then, when the electrode was charged to 2 V, the first-step reversal reaction occurred. First, the diffraction peak of KP at 30.8° became significantly wider and smaller, and the peak of K<sub>2</sub>S<sub>3</sub> appeared, indicating that the KP reversal conversion product formed. Finally, when the voltage reaches 3 V, only the switching phase of K<sub>2</sub>S<sub>3</sub> and K<sub>2</sub>S<sub>4</sub> can be observed, so we infer that this is a reversible switching reaction. For some phases with poor crystallinity, we applied XPS and Raman for qualitative analysis. The ex-situ Raman spectra at discharge state and charge state is

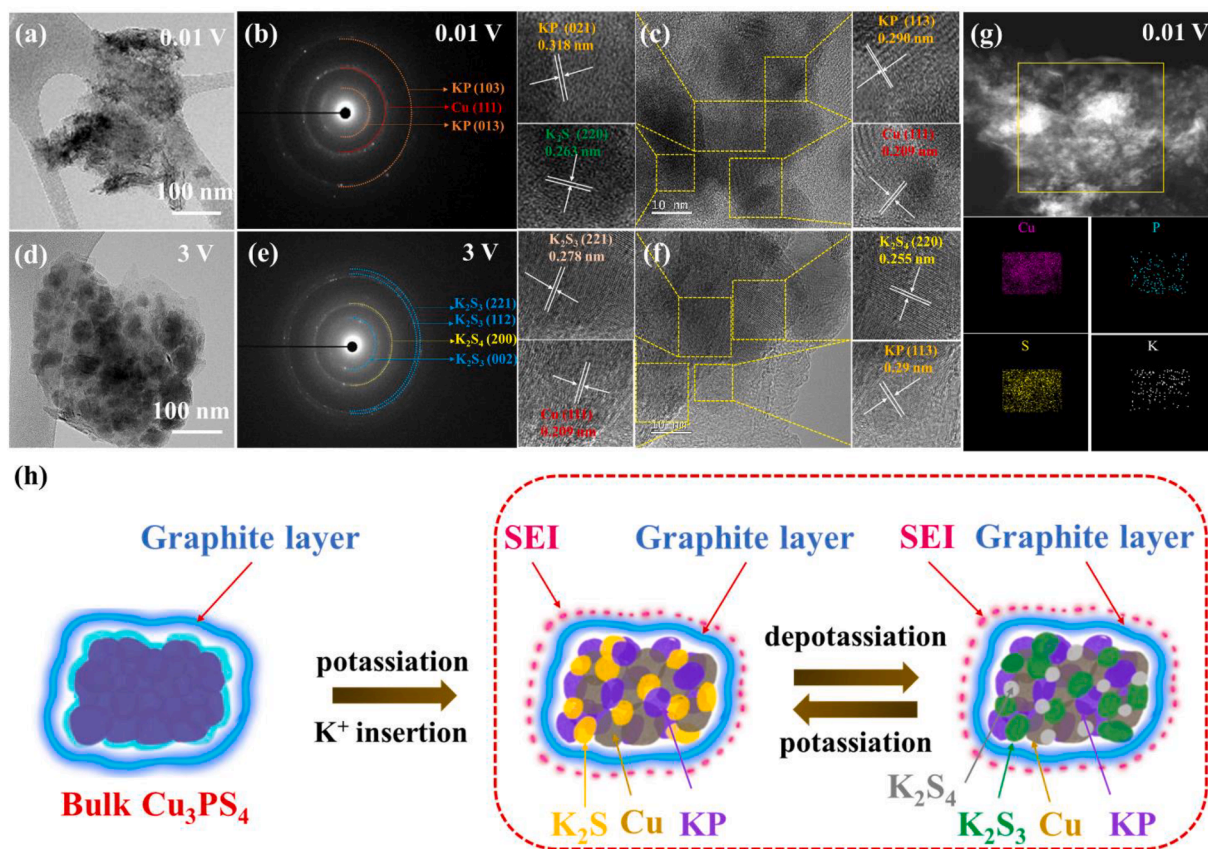

**Fig. 3.** Ex-situ analysis of the reaction mechanism of  $\text{Cu}_3\text{PS}_4$ . (a) Ex-situ XRD pattern at various stages of discharge(A-C)-charge(D-G) and the corresponding T-V curves. (b) Ex-situ Raman spectra at various stages of charge–discharge reactions. (c–e) Ex-situ XPS spectra at fully-discharged (0.01 V) and charged (3 V) state of Cu 2p, P 2p, S 2p orbital. (f) Schematic illustration of the multiple reaction mechanism of  $\text{Cu}_3\text{PS}_4/\text{G}$ . The crystal structure displays the reaction product at different stage.

exhibited respectively (Fig. 3b). A peak of  $\text{K}_2\text{S}_x$  appears at  $270 \text{ cm}^{-1}$  of Raman shift, and the  $450 \text{ cm}^{-1}$  peak when discharging to 0.01 V can be referred to  $\text{K}_2\text{S}$ . While the electrode charge back to 1.5 V, the reversible conversion reaction occurs, showing similar peak compared with the discharge curve. As a result,  $\text{K}_2\text{S}$  is being deduced also as a final product of the conversion reaction. To further elucidate the perspective, we used ex-situ XPS to see the valence state of electrode (Fig. 3c–e). The binding energies of 932.5 eV and 952.5 eV correspond to 0-valent copper and 1-valent copper (Fig. 3c), confirming the exsolution of copper [69]. In addition, it shows that the state of complete de-potassiation of monovalent copper and zero-valent copper still exists at the electrode, which confirms the inference of reversible conversion reaction. The phosphate formed at the binding energy of 132 eV may be KP phase (Fig. 3d). Moreover, thiosulfate generated at the binding energy of 167.5 eV and

171.5 eV for charging and discharging, respectively; and the peak at the binding energy of 161.5 eV is indexed to the phase state of  $\text{K}_2\text{S}$  (Fig. 3e). Finally, we demonstrate the crystal structure of the corresponding phase during charge–discharge process (Fig. 3f). It is evident of a reversible conversion reaction occurred after the 1st discharge.

To further elucidate the phase evaluation during reaction mechanism, we examine the fully charged (3 V) and discharged products (0.01 V). First, the visual topography uniformly wrapped by layered graphite at a fully discharged state is shown (Fig. 4a), indicating that the structure remains intact after complete chemical reaction. The SAED pattern can be assigned to (1 0 3) and (0 1 3) facets of KP, and (1 1 1) facet of Cu phase, consistent with the *ex-situ* XRD and *ex-situ* XPS results (Fig. 4b). The HRTEM image (Fig. 4c) clearly demonstrate the products of the conversion reaction after potassium ion insertion, agreeing with the

**Fig. 4.** Ex-situ TEM at fully potassiated (0.01 V) and de-potassiated (3 V) state of Cu<sub>3</sub>PS<sub>4</sub>/G. (a-c) TEM image, SAED pattern, and HRTEM image of Cu<sub>3</sub>PS<sub>4</sub>/G at 0.01 V. The yellow region insets in HRTEM display multiple junctions of the discharge product. (d-f) TEM image, SAED pattern, and HRTEM image of Cu<sub>3</sub>PS<sub>4</sub>/G at 3 V. The yellow region insets display multiple junctions of the charge product. (g) EDS mapping obtained at 0.01 V, showing the distribution of copper, phosphorus, sulfur, and potassium elements. (h) Schematic illustration of the morphological structure view during potassium ion insertion/extraction.

results of ex-situ XRD and XPS. At d-spacings of 0.263 nm and 0.318 nm, the lattice fringes of the conversion product can be assigned to the (220) plane of K<sub>2</sub>S and the (021) plane of KP. In addition, the d-spacing of 2.09 Å can correspond to the (111) plane of Cu, confirming the existence of the reduction reaction of 0-valent copper. Furthermore, the fringe can be separated into adhesive junction, implying a tight contact among various phases. On the other hand, during the charging process, the low-magnification TEM image (Fig. 4d) shows that the electrode material formed a composite uniformly coated layered structure with a bulk-like morphology aggregated in the center. The SAED pattern (Fig. 4e) shows three distinct diffraction rings, corresponding to Cu (111), K<sub>2</sub>S (200), K<sub>2</sub>S<sub>3</sub> (200), respectively. The lattice fringe spacing of the reversibly transformed phase is shown (Fig. 4f), and their interplanar spacing is 0.278, 0.255, 0.209, and 0.29 nm, which corresponds to the crystal plane of K<sub>2</sub>S<sub>3</sub> (221), K<sub>2</sub>S<sub>4</sub> (220), Cu (111), and KP (113), respectively. In addition, the corresponding databases of K<sub>2</sub>S, K<sub>2</sub>S<sub>3</sub>, KP and Cu have been attached in the [supplementary information](#). It is worth mentioning that for Cu<sub>3</sub>PS<sub>4</sub>/G, in the reversible conversion reaction, the precipitation of copper is important and reasonable: in addition to allowing the electrode material to form a uniform composite, it can also improve the conductivity of the overall electrode. Finally, the HAADF image and EDS mapping results of Cu<sub>3</sub>PS<sub>4</sub>/G discharged to 0.01 V are shown (Fig. 4g), indicating the presence of copper, phosphorus, sulfur, and potassium without phase separation. By integrating the results of XRD, XPS, Raman spectra and TEM, we propose the following integrated equation:

Reduction.

Stage I:  $\text{Cu}_3\text{PS}_4 + 3\text{K}^+ + 3\text{e}^- \rightarrow \text{KP} + 3\text{Cu} + \text{K}_2\text{S}_4 + \text{SEI formation} \sim 1.5\text{ V}$

Oxidation

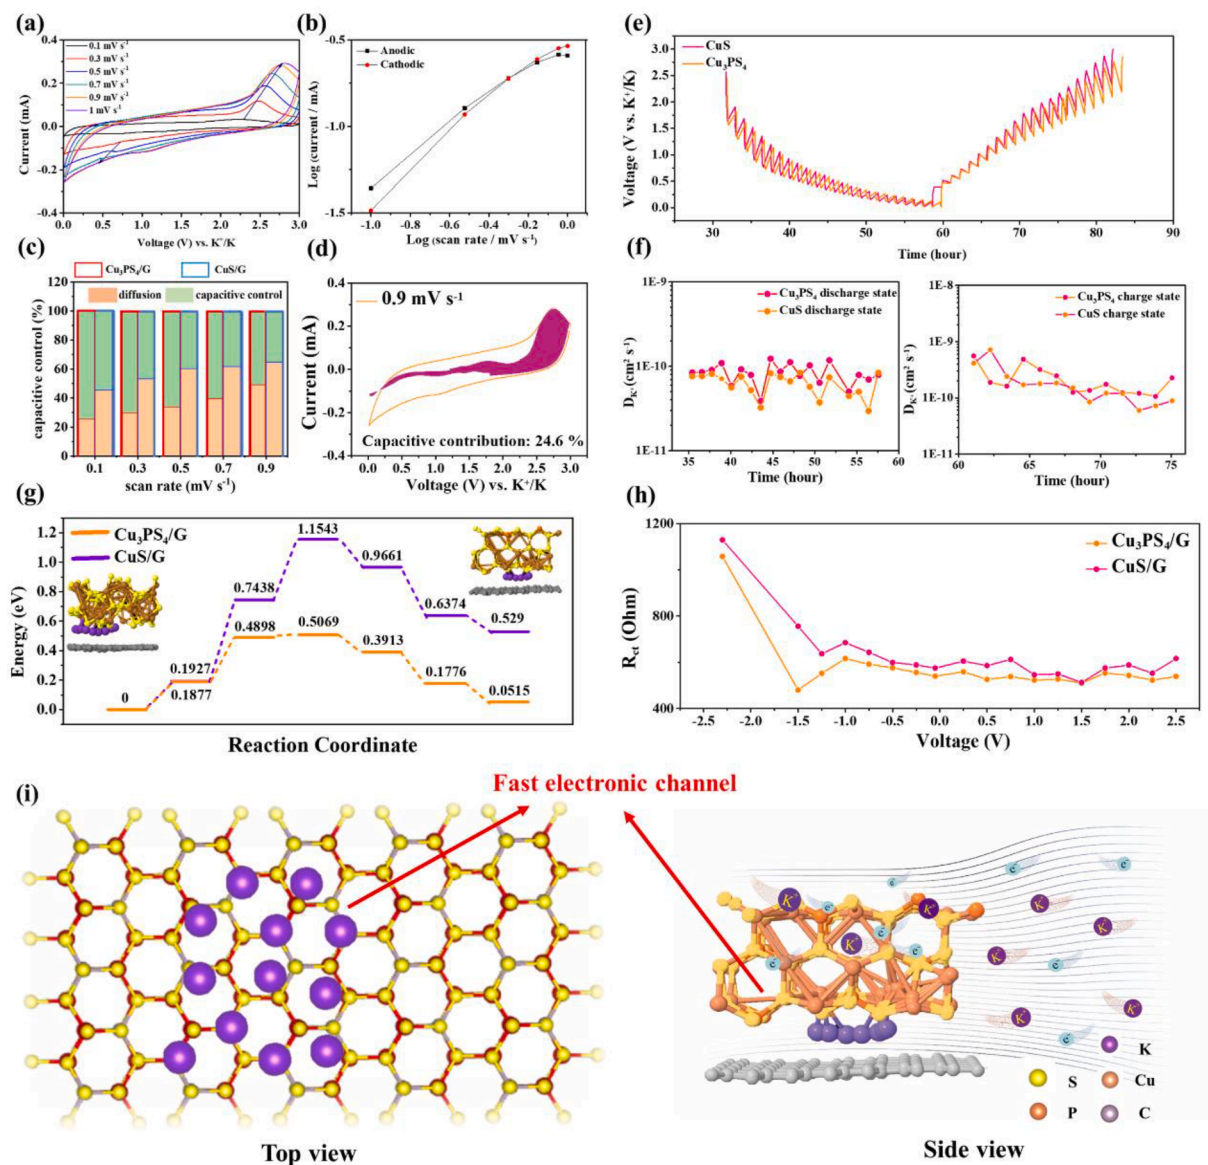

Finally, we exhibit the overall reaction path accompanied with the corresponding structure (Fig. 4h). During the potassiation process, a junction formed tightly and different discharge phases adhere with the other phases. Moreover, the reversible conversion reaction allows the existence of junction and the stable graphite layer prevent the collapse of structure.

#### 2.4. Kinetic analysis of Cu<sub>3</sub>PS<sub>4</sub>/G

The excellent K<sup>+</sup> storage capacity and long-term cycling performance of Cu<sub>3</sub>PS<sub>4</sub>/G may be related to the pseudo-capacitance and diffusion behaviors at different rates. We measured and calculated its pseudocapacitive contribution by cyclic voltammetry (CV) at different scan rates, varied from 0.1 mV s<sup>-1</sup> to 0.9 mV s<sup>-1</sup> (Fig. 5a). The curves have similar shapes and trends, indicating that the electrochemical process in the electrode is rapid and reversible, with no obvious phase transition. To determine whether the current is dominated by surface reaction or diffusion reaction can be judged by the following formula:

$$i_p = av^b (b = 0.5 \sim 1.0) \quad (1)$$

where a and b are power-law variables, *i<sub>p</sub>* corresponds to the peak current, and *v* is the scan rate. In addition, the b value is relatively more

**Fig. 5.** Kinetic performance and potassium ion diffusion experiment of  $\text{Cu}_3\text{PS}_4/\text{G}$ . (a) CV curves at various scan rates. (b) Linear fitting profiles of  $\log(i, \text{peak current})$  vs  $\log(v, \text{scan rate})$ . (c) Capacitance contribution of  $\text{CuS}/\text{G}$  and  $\text{Cu}_3\text{PS}_4/\text{G}$ . (d) The integral area of  $\text{Cu}_3\text{PS}_4/\text{G}$  displaying the potassium ion diffusion-controlled contribution at  $0.9 \text{ mV s}^{-1}$ . (e) GITT curves of  $\text{CuS}/\text{G}$  and  $\text{Cu}_3\text{PS}_4/\text{G}$  at  $50 \text{ mA g}^{-1}$ . (f) The diffusion coefficient calculated from the obtained GITT results. (g) DFT calculation of potassium ion diffusion energy barrier of  $\text{CuS}/\text{G}$  and  $\text{Cu}_3\text{PS}_4/\text{G}$ . (h) The top view and side view of electron-ion diffusion through ionic channel in orthorhombic  $\text{Cu}_3\text{PS}_4/\text{G}$  crystal structure.

important in this formula since after taking the logarithm, the slope  $b$  value shows the kinetic contribution of the electrode surface. By taking the main peaks of the cathode and anode, their corresponding slope  $b$  values can be calculated to be 0.88 and 0.81, respectively (Fig. 5b). Therefore, we further use CV plots of different scan rates to quantify the contribution of the capacitive effect to the electrode as the diffusion control of potassium ion insertion or the contribution of the double layer capacitance. We use the relational equation for the calculation:

$$i = k_1 v + k_2 v^{0.5} \quad (2)$$

$$i/v^{0.5} = k_1 v^{0.5} + k_2 \quad (3)$$

Among them,  $k_1 v$  of formula (2) represents the non-faraday reaction, while  $k_1 v^{0.5}$  represents the faraday reaction. By calculating the slope of  $k_1$  and the intercept of  $k_2$  and doing linear fitting, the main peak is the capacitive contribution of the reaction current at constant potential and the diffusion contribution. The capacitance contributions at different

scan rates are shown (Fig. 5c), and the results show that the capacitance contributions from  $0.1 \text{ mV s}^{-1}$  to  $0.9 \text{ mV s}^{-1}$  are 25.6, 29.7, 33.9, 39.5, and 49.9 %, respectively. On the other hand, the  $\text{CuS}/\text{G}$  electrode is dominated by capacitive control; its capacitance contribution ratio corresponded to the CV curves at different scan rate (Fig. S8) is 45.5, 53.3, 60.2, 61.7, 64.9 %, respectively. Additionally,  $\text{Cu}_3\text{PS}_4/\text{G}$  also shows an 81.9 % capacitive control ratio at  $0.5 \text{ mV s}^{-1}$  (Fig. S9), explaining that layer graphite act as a superior electronic channel for potassium ion diffusion. In spite of a high contribution ratio, the  $\text{Cu}_3\text{PS}_4/\text{G}$  electrode fails to reach good reversibility at high current density due to poor diffusivity. The closed region of the CV curve fit at  $0.9 \text{ mV s}^{-1}$  is shown (Fig. 5d), the percentage of the enclosed area relative to the total area is 49.9 %, suggesting capacitance-controlled current is smaller than the surface-diffusion-controlled current, so that the kinetic reaction of the electrode is dominated by the diffusion-controlled current. According to the recent reports, electrodes are more likely to lose capacitance due to diffusion, and electrodes tend to contribute more to capacitance

at high current densities. However, high diffusion coefficient may allow potassium-ions to diffuse efficiently in the system, as a result, we utilize galvanostatic static intermittent titration (GITT) to further provide diffusion coefficients. The diffusion coefficient of GITT can be obtained from its curve and calculated by the following formula:

$$D_K^+ = 4/(\pi\tau)L^2((\Delta E^s)/(\Delta E_t))^2 \quad (4)$$

where  $\tau$ ,  $\Delta E_s$ ,  $\Delta E_t$ , and  $L$  are denoted as the current pulse time (s), the constant voltage change induced by the current pulse, the potential change in the steady-state current pulse, and the electrode thickness, respectively. The GITT curve of  $\text{Cu}_3\text{PS}_4/\text{G}$  and  $\text{CuS}/\text{G}$  at a relaxation time of 20 min is shown (Fig. 5e), while the calculated diffusion coefficient value is shown (Fig. 5f). The diffusion coefficient is between  $10^{-9}$  and  $10^{-11}$ , and is closer to  $10^{-10}$  ( $\text{cm}^2 \text{s}^{-1}$ ), which is higher than the value of  $\text{CuS}$ . In addition, the decrease in diffusion coefficient during potassium intercalation can be attributed to the influx of bulk potassium ions, resulting in structural expansion. Even so,  $\text{Cu}_3\text{PS}_4/\text{G}$  exhibits excellent diffusion behavior, corresponding to previous capacitive contribution tests, explaining how the electrode retains reversible capacitance under diffusion control and exhibits outstanding rate capability. In order to gain insight into how the reaction kinetics of potassium-ions in the electrode-material interface affects ion diffusion, we carried out density functional theory (DFT) calculations to study the  $\text{K}^+$  storage capacity and the internal energy barrier coefficient. First, the construction models of  $\text{Cu}_3\text{PS}_4/\text{G}$  and  $\text{CuS}/\text{G}$  are shown (Fig. 5g). It is worth mentioning that these models all calculate similar total energies, indicating relative stability in the natural state. In addition, we select the (220) crystal plane observed by HRTEM, constructed a potassium ion transport channel, and simulated its possible diffusion pathway, and calculated the associated migration energy. We can find that the  $\text{Cu}_3\text{PS}_4/\text{G}$  has a lower site energy of 1.2 eV than that of  $\text{CuS}/\text{G}$ , which is approximately 0.5 eV in diffusion pathway, proving that the  $\text{Cu}_3\text{PS}_4/\text{G}$  possesses a faster ion diffusion due to low energy barrier especially at the surface, which is also coherent to the results measured by GITT. The above result may also be corresponded with the diffusivity of binary  $\text{CuS}/\text{G}$  and ternary  $\text{Cu}_3\text{PS}_4/\text{G}$ , demonstrating the advantage of  $\text{Cu}_3\text{PS}_4/\text{G}$  during chemical reaction, so that  $\text{Cu}_3\text{PS}_4/\text{G}$  is able to perform a better electrochemical performance than  $\text{CuS}/\text{G}$ . Finally, the resistance of the electrode is reduced and the capacitance value of the diffusion loss can be compensated. To confirm this inference, we used ex-situ electrochemical impedance spectroscopy (EIS) to measure the resistance change of  $\text{Cu}_3\text{PS}_4/\text{G}$  before electrochemical reaction. Before cycling, the  $R_{ct}$  of  $\text{Cu}_3\text{PS}_4/\text{G}$  is significantly large, about 4000 Ohm (Fig. S10). Furthermore, we used the in situ electrochemical impedance spectroscopy to test the continuous variation of  $R_{ct}$  value of  $\text{Cu}_3\text{PS}_4/\text{G}$  (Fig. 5h). The above results shows that the barriers to charge transfer and diffusion of  $\text{Cu}_3\text{PS}_4/\text{G}$  are extensively reduced during potassiation/depotassiation. When discharging from OCV to 1.75 V, the  $R_{ct}$  value of the electrode is large and continues to rise when discharging to 1.25 V due to the formation of the SEI layer and the irreversible conversion reaction; however, when the electrode is fully discharged (0.01 V), its  $R_{ct}$  is reduced to about 500 Ohm again. To image the above-mentioned results and understand the fast diffusion during charge-discharge process, we illustrate the  $\text{Cu}_3\text{PS}_4/\text{G}$  crystal structure in various angle. The top view and the side view of the potassium ion diffusion pathway are proposed (Fig. 5i). The large potassium ions are able to mobile through the crystal, and the layer graphite provides an electronic channel for electrons and ions since more active sites enhance redox reaction process. Therefore, the electrodes can sustain at a high current density, behave a superior potassium ion storage, and reduce the hinderance of the structure during chemical reaction.

## 2.5. Potassium polysulfides adsorption experiment

We conducted a chemical adsorption method to show the intense

entrapment effect of pristine  $\text{Cu}_3\text{PS}_4$ ,  $\text{CuS}$  (Fig. S11),  $\text{Cu}_3\text{PS}_4/\text{G}$ , and  $\text{CuS}/\text{G}$  composite toward potassium polysulfides. The experiments were executed by adding 30 mg  $\text{K}_2\text{S}$  to 5 ml DMC solution, and after a well dispersion, 40 mg of the testing material was added separately to start a 4-hour suspension (Fig. 6a). It is obvious that after 4 hours, the color of  $\text{K}_2\text{S}$  contained electrolyte with  $\text{Cu}_3\text{PS}_4/\text{G}$  and pristine  $\text{Cu}_3\text{PS}_4$  transformed from light yellow to pure solution, whereas  $\text{CuS}/\text{G}$  has inconspicuous color difference compared with the original state. Thus, the result implies that  $\text{Cu}_3\text{PS}_4/\text{G}$  performs a stronger interaction with potassium poly-sulfates, while  $\text{CuS}/\text{G}$  composite exhibited ineffective entrapment effect. Moreover, we constructed various polysulfides ( $\text{K}_2\text{S}_x$ ) and simulated the adsorption energies of the two materials for these polysulfides. The simulation result in a bar chart is demonstrated (Fig. 6b), and the adsorption energies of  $\text{Cu}_3\text{PS}_4/\text{G}$  to polysulfides are smaller than the value of  $\text{CuS}/\text{G}$  (Fig. 6c). Although the adsorption energy of  $\text{Cu}_3\text{PS}_4/\text{G}$  is not as high as that of  $\text{CuS}/\text{G}$ , in a typical chemical reaction,  $\text{K}_2\text{S}_x$  experience the de-sulfurization steps, which are all elementary reactions, while the active material serves as active sites to accelerate the decomposition of  $\text{K}_2\text{S}_x$ . As a result, the adsorption energy should maintain in a certain range of value without over-fluctuating to enable the electrode to react effectively. In this case, the utilization of sulfur can be enhanced during phase transformation, and thus improve the electrochemical performance.

## 2.6. In-depth discussion between the electrochemical result and analysis

Therefore,  $\text{Cu}_3\text{PS}_4/\text{G}$  has an unique kinetic behavior and the special material science during chemical reaction. During the charge and discharge process of the battery, ions and electrons will participate in chemical reactions in multiple diffusion paths that are beneficial to each other. From the results provided by DFT, we conclude that the material has good rate capability due to its excellent potassium ion diffusivity, which can effectively transfer charges even at very high current densities. In addition, we can infer that  $\text{Cu}_3\text{PS}_4/\text{G}$  not only can absorb polysulfides but also prevent them from dissolving in the liquid electrolyte. The  $\text{Cu}_3\text{PS}_4/\text{G}$  has a relatively stable chemical reaction to enable the material to capture the polysulfides generated during charge/discharge process and expand the utilization efficiency of  $\text{K}_2\text{S}_x$ , guaranteeing an ultra-stable electrode during cycling process. During the charge and discharge process, ions and electrons will participate in chemical reactions in multiple diffusion paths that are beneficial to each other. Through the effective diffusion paths simulated by DFT calculations, it is known that the formation of  $\text{Cu}_3\text{PS}_4/\text{G}$  along the diffusion pathway of the z-axis of the intersecting structure has the lowest diffusion energy barrier. Moreover, it has been suggested that more synergistic elements in the ternary material can provide a better ion exchange mechanism in the process of potassiation/de-potassiation of potassium ions, and increase different active sites, thereby enhancing the chemical reaction rate. Based on the above theoretical and experimental results, it can be concluded that potassium ions have outstanding diffusion ability in  $\text{Cu}_3\text{PS}_4/\text{G}$  anode compared with  $\text{CuS}$ , and the ratio of diffusion to capacitance contribution at high scan rate is close to 1:1, still possessing excellent rate performance. Despite that several studies related to the material based on diffusion control have demonstrated instability and capacitance loss at high current densities since the electrode may act as a capacitor and dominated by capacitive. However, due to the operation of the synergistic ion exchange mechanism and the open channels provided by orthorhombic  $\text{Cu}_3\text{PS}_4$ , it is possible to exhibit a fast Faradaic charge transfer process and excellent ion diffusion performance. Even at high current densities, the  $\text{Cu}_3\text{PS}_4$  electrodes still maintain stable reversible reactions, which is rare in cases of diffusion-controlled based pseudocapacitive contributions. In addition, the diffusion coefficient of  $\text{Cu}_3\text{PS}_4$  is one order of magnitude larger than that of  $\text{CuS}$ , which is  $10^{-9}$   $\text{cm}^2 \text{s}^{-1}$ , and the diffusion energy barrier in each direction is much lower than that of  $\text{CuS}$ . These results enable the electrode to provide excellent charge storage performance and ion-electron transfer. By creating an

(b) The corresponding adsorption energy of  $\text{CuS}/\text{G}$  and  $\text{Cu}_3\text{PS}_4/\text{G}$  plotted corresponded with the DFT calculation result. (c) Crystal model of the potassium polysulfides adsorption of  $\text{CuS}/\text{G}$  and  $\text{Cu}_3\text{PS}_4/\text{G}$  with their adsorption energy.

optimal tunnel for ion and electron passage, large potassium ions can mobile rapidly in the structure to improve sluggish kinetics that often occurs in metal sulfides and accumulates electrons on the surface of the structure, resulting in a more excellent surface charge effect.  $\text{Cu}_3\text{PS}_4$  not only provides a larger ionic contact area than binary  $\text{CuS}$ , but also increases the redox active sites in electrochemical reactions. The low resistance and diffusion energy barrier make the electrode perform better in long-term cycle test, rate performance, and even promotes energy density in potassium ion battery full-cell and potassium ion hybrid capacitor applications. This reveals  $\text{Cu}_3\text{PS}_4$  a superior electronic channel that optimizes the electrochemical performance of materials, utilizes a fast ion-exchange mechanism to boost the performance of metal sulfides in PIB systems, and provides new insights into all materials whose pseudocapacitive behavior is diffusion-controlled.

## 2.7. Potassium-ion full battery and hybrid capacitor

Based on the excellent electrochemical performance of  $\text{Cu}_3\text{PS}_4/\text{G}$  in

half cells and its superior diffusivity ameliorating the redox shuttle effect which often occurs in chalcogenide electrodes, we combined it with the common cathode materials in potassium ion energy storage systems to assemble PIBs full coin cell. Due to the high oxidation potential of the conversion product  $\text{K}_2\text{S}$ , some cathode materials such as  $\text{PTCDA}$  [70],  $\text{KVPO}_4\text{F}$  [71] cannot meet the working voltage exceeding 3.5 V; as a result, Prussian analogs with high working voltage and stable capacitance such as  $\text{KFeHCF}$  [72,73],  $\text{KMnHCF}$  [74] and  $\text{KNiHCF}$  [75] are used a lot in recent studies. The schematic diagram of the reaction of the potassium ion full battery system is shown (Fig. 7a), in which the Prussian blue synthesized through the precipitation method which has a stable spinel structure, and can stably receive potassium ions diffused from the negative electrode. The SEM images and XRD pattern are shown (Fig. S12 – Fig. S13), respectively, which proves that Prussian blue corresponded to the database can be confirmed. The CV curves of the  $\text{Cu}_3\text{PS}_4/\text{G}/\text{KFeHCF}$  full cell are plotted at a scan rate of  $0.1 \text{ mV s}^{-1}$  (Fig. 7b), and it can be seen that there is an oxidation reaction at the first charge near 3.85 V, which is the solid-electrolyte interface film

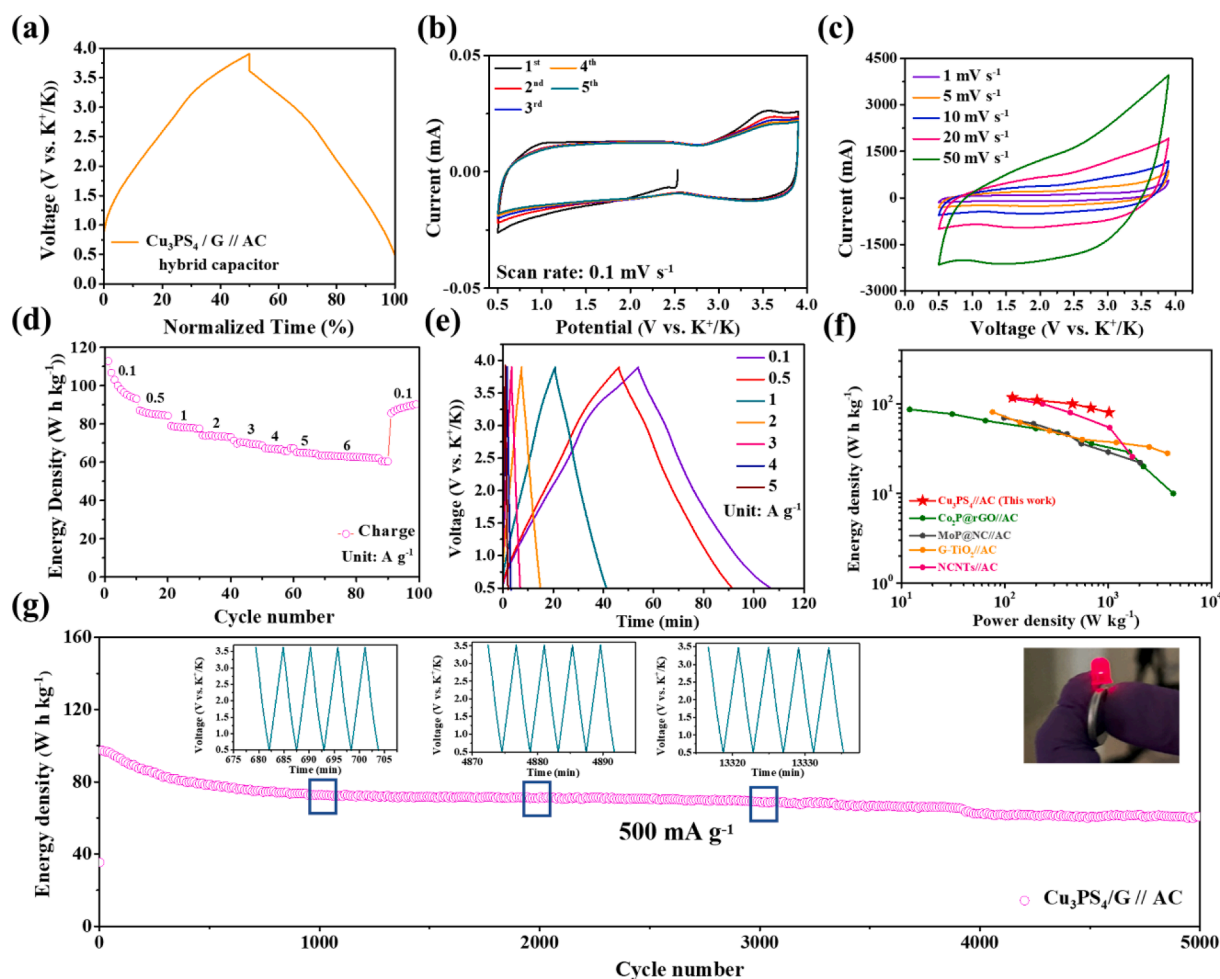

**Fig. 7.** Potassium ion coin type full cell of  $\text{Cu}_3\text{PS}_4/\text{G} // \text{PB}$ . (a) Schematic illustration of the full cell operation. (b) CV curves of the full cell at 1st ~ 5th cycle. (c) QV curves of PB cathode,  $\text{Cu}_3\text{PS}_4/\text{G}$  anode and full cell. (d) Rate performance at seven different current densities. (e) GCD curves plotted corresponded to rate performance. (f) Long-term cycling performance at  $120 \text{ mA g}^{-1}$  and LED light demo.

formation. After the second lap, the CV curves are all well-overlapped, showing the high reversibility of the chemical reaction, and the redox reaction of the conversion in the anode provides a lot of specific capacity. In addition, we also measured the rate performance of the  $\text{Cu}_3\text{PS}_4/\text{G} // \text{KFeHCF}$  full cell (Fig. 7d) at 30, 75, 120, 150, 300, 450, 750  $\text{mA g}^{-1}$ , providing capacities of 58, 39, 37, 30, 27, 25, 20  $\text{mA h g}^{-1}$ , respectively. The discharge capacity loss in each interval is about 5–10%. When the current density returned to  $75 \text{ mA g}^{-1}$ ,  $\text{Cu}_3\text{PS}_4/\text{G} // \text{KFeHCF}$  still had a discharge capacity of  $42.5 \text{ mA h g}^{-1}$ . Even at high current densities, there would be a slight overpotential shift, resulting in a plateau shift, the  $\text{Cu}_3\text{PS}_4/\text{G}$  and Prussian blue still exhibit excellent energy density, while the GCD curves plotted corresponded to the as-tested rate performance at various current densities are shown (Fig. 7e). Finally, our long-term cycle tests based on the total active material weight (Fig. 7f) illustrates that the full cell of PIBs of  $\text{Cu}_3\text{PS}_4/\text{G} // \text{KFeHCF}$  can maintain a cycle life of 800 cycles at a current density of  $120 \text{ mA g}^{-1}$  and possess  $57 \text{ mA h g}^{-1}$  of the reversible capacity. In addition, a fully charged (3.99 V) button-type full battery can be assembled and applied to a LED light demo as shown in the inset of Fig. 7f, which further proves the application potential of the full cell.

Furthermore, we assembled a potassium-ion hybrid capacitor composed of a  $\text{Cu}_3\text{PS}_4/\text{G}$  anode and an activated carbon (AC) cathode. With the fast diffusion of potassium ions in the composites and excellent kinetic properties, the FSI-ions in the electrolyte can undergo a Faradaic

reaction on the surface of the anode through electrochemical double-layer capacitance (EDLC), and then react on the activated carbon on the surface of the cathode by adsorption and desorption to obtain high energy density. Before assembling the PIHC, we preactivated the  $\text{Cu}_3\text{PS}_4/\text{G}$  of the anode for 20 cycles in order to activate the electrode, so that the interior of the material is inserted with potassium ions. Considering the decomposition of the electrolyte at high working voltage, we set the working range at 0.5–3.9 V. The GCD curve is shown (Fig. 8a), and the curve slightly forms a non-isosceles triangle from the ideal triangular shape, which is a reasonable platform displacement and also demonstrates the additional contribution of the pseudo-capacitance to the charge storage. The CV curves of PIHC exhibits a typical capacitive behavior compared with the obvious redox peak in the half-cell due to the complete adsorption–desorption physical reaction (Fig. 8b), which also proves that no other side reactions occur at the working electrode. In addition, CV curves at various scan rates are shown (Fig. 8c) to perform the capacitance contribution. On the other hand, we tested the rate capability of PIHC, based on the total weight of  $\text{Cu}_3\text{PS}_4/\text{G}$  and active carbon (Fig. 8d), the energy density of 92, 85, 79, 73, 70, 69, 63  $\text{W h kg}^{-1}$  at current densities of 0.1, 0.5, 1, 2, 3, 4, 5, 6  $\text{A g}^{-1}$ , respectively. When the current density was restored to  $0.1 \text{ A g}^{-1}$ , the energy density of PIHC could still reach  $89 \text{ W h kg}^{-1}$ , showing its extraordinary reversibility. In addition, we compare the energy density and power density of PIHC of chalcogenide anodes in recent years

**Fig. 8.** Potassium ion coin type hybrid capacitor of  $\text{Cu}_3\text{PS}_4/\text{G} // \text{AC}$ . (a) Normalized GCD curves of the PIHC. (b) CV curves at  $0.1 \text{ mV s}^{-1}$  at 1st ~ 5th cycle. (c) CV curves of PIHC at various scan rates. (d) Rate performance. (e) Normalized GCD curves plotted corresponded to rate capability. (f) Ragone plot of recent researches of PIHC. (g) Long-term cycling performance at  $500 \text{ mA g}^{-1}$  and LED light demo. The inset displays the normalized GCD curves at 1000th, 2000th, and 3000th cycle.

through Ragone diagram (Fig. 8f). The long-term cycling performance of PIHC at  $500 \text{ mA g}^{-1}$  is demonstrated (Fig. 8g), which provides an energy density of  $80.3 \text{ Wh kg}^{-1}$  for over 5000 cycles with 76 % energy density retention, and the battery was applied to LED light demo, showing its potential at energy storage device. Furthermore, we show that the  $\text{Cu}_3\text{PS}_4/\text{G} // \text{AC}$  performed an energy density of  $57 \text{ Wh kg}^{-1}$  at high current density (Fig. S15), and using 1 M KFSI in DMC as the electrolyte may be more stable for the hybrid capacitor system than choosing 4 M KFSI DME. Based on the outstanding potassium ion diffusivity and sufficient potassium sulfide adsorption energy, the material has excellent performance in hybrid capacitors.

### 3. Conclusion

This study proposes an electrode with efficient potassium ion diffusion to create a fast ionic channel during charge and discharge, suggesting the synergistic effect of multi-elements in orthorhombic  $\text{Cu}_3\text{PS}_4/\text{G}$  to promote the highly-reversible conversion reaction of elements to perform capacities  $>600 \text{ mA h g}^{-1}$ . Compared with some materials whose capacitance contribution is dominated by surface reaction,  $\text{Cu}_3\text{PS}_4/\text{G}$  enhances charge transfer through fast ion–electron reaction channels, reduces electrode resistance, and increases the diffusion coefficient of potassium-ions by an order of magnitude, achieving  $10^{-9} \text{ cm}^2 \text{ s}^{-1}$ , and exhibits excellent rate performance that can withstand high current densities of  $8 \text{ A g}^{-1}$ . In addition, the lattice model of potassium ions during diffusion was simulated by the density functional theory,

and the difference in the diffusion energy barrier of ternary and binary metal sulfides was compared by the results calculated by the energy barrier, and it was explained that effective adsorption energy of potassium polysulfides, interactively verified the experimental results. During the potassiation–de-potassiation process, it forms a distinct and tight junction to illustrate the structure remains unchanged after charge and discharge, and generates a phase state that provides stable reversible capacitance. Finally, we successfully demonstrated that  $\text{Cu}_3\text{PS}_4/\text{G}$  have high energy density and Coulomb efficiency in hybrid capacitors and batteries, giving a proof-of-concept in new energy storage devices. This research not only brings a new perspective in the use of ternary metal sulfides in high-efficiency potassium ion electrode materials, but also solves the shuttle effect and sluggish kinetics that often occur in K-S batteries.

### 4. Experimental section

#### 4.1. Chemicals and materials

Commercial copper particles (less than  $425 \mu\text{m}$ , 99.5 % purity), phosphorus pentasulfides ( $>99 \%$  purities), Copper sulfate pentahydrate, were purchased from Sigma-Aldrich. Sulfur powder ( $>99 \%$  purities) was purchased from Alfa-Aesar.

#### 4.2. Preparation of $\text{Cu}_3\text{PS}_4$

In a typical synthesis process, 6 mmol of commercial copper particles, 1 mmol of  $\text{P}_2\text{S}_5$ , and 3 mmol of sulfur were ball-milled in a planetary jar containing 4 zirconium balls for 24 h at 400 rpm. For the use of ball mill, the ball to powder weight ratio was set to 5: 1.

#### 4.3. Preparation of $\text{Cu}_3\text{PS}_4/\text{G}$ composites

The  $\text{Cu}_3\text{PS}_4/\text{G}$  composites were synthesized by adding 100 mg the as-synthesized  $\text{Cu}_3\text{PS}_4$  powder and 30 mg graphite in a zirconium jar, and then ball mill for 12 h at 400 rpm.

#### 4.4. Synthesis of CuS nanoparticles

The CuS nanowires were synthesized via a solvothermal method. Typically, 1 mmol copper pentasulfides and 2 mmol of thiourea powder were dissolved in 50 ml DI water. The solution was fully-mixed until it formed a clear solution, and the obtained solution was transferred into a Teflon-lined in an autoclave for 2 h. The black precipitation was centrifugated by absolute ethanol for five times and dried at 80 for further use.

#### 4.5. Synthesis of CuS/G composites

The CuS/G composite were prepared via a ball-milling process. First, 100 mg of the as-synthesized CuS were added with 33 mg of graphite in a zirconia jar. Then 400 rpm ball-milling process was applied for 12 h.

#### 4.6. Synthesis of $\text{K}_x\text{Fe}[\text{Fe}(\text{CN})_6] \cdot y \text{H}_2\text{O}$

In a typical synthesis process, 5 mmol of  $\text{FeCl}_2 \cdot 4 \text{H}_2\text{O}$  was dissolved in 100 ml of DI water to be solution A, while 5 mmol of  $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3 \text{H}_2\text{O}$ , 10 mmol potassium citrate, and excess potassium chloride were dissolved in DI water to form solution B. Then, solution A was slowly added into solution B by precipitation method, and waited for a six-hour suspension. After that, the product was centrifugated and washed for three times with a mixture of DI water, and finally dried at 80 °C in a CVD for 2 h.

#### 4.7. Electrochemical characterization

The  $\text{Cu}_3\text{PS}_4/\text{G}$  nano-composite electrodes were fabricated by mixing the active material ( $\text{Cu}_3\text{PS}_4/\text{G}$ , 70 wt%), super P (20 wt%), and sodium carboxymethyl cellulose (NaCMC, 10 wt%) in 0.5 ml de-ionized water to form a homogeneous slurry that has 9.5 % solid content. Then, the slurry was casted on the copper foil and dried at 80 °C under argon atmosphere for 90 min to remove residual water and excess solvent. Before coin cell assembly, the electrode is shaped to a circle with 12 mm diameter and densely pressed with a rolling machine. All coin cells were assembled in an argon-filled glove box. We used 1 M KFSI dissolved in 10 ml dimethyl carbonate (DMC) as the electrolyte for potassium-ion half coin cell. Finally, electrochemical performance of  $\text{Cu}_3\text{PS}_4/\text{G}$  is tested using Neware series and VMP3 instrument.

#### 4.8. Computational section

The present first principle DFT calculations are performed by Vienna Ab initio Simulation Package (VASP) [1] with the projector augmented wave (PAW) method [2]. The exchange-functional is treated by generalized gradient approximation (GGA) of Perdew-Burke-Ernzerhof (PBE) [3] functional. The energy cutoff for the plane wave basis expansion was set to 450 eV and the force on each atom less than 0.02 eV/Å was set for convergence criterion of geometry relaxation. 15 Å vacuum was added along the z direction in order to avoid the interaction between periodic structures. The Brillouin zone integration are sampled by single  $\Gamma$  point

for both CuS-graphite and  $\text{Cu}_3\text{PS}_4$ -graphite, respectively. The self-consistent calculations apply a convergence energy threshold of  $10^{-5}$  eV. The DFT-D3 method was employed to consider the van der Waals interaction [4]. Transition state searching were calculated using the climbing-image nudged elastic band (CI-NEB) method [5]. The adsorption energy of  $\text{K}_2\text{S}_x$  molecules were calculated according to.

$$E_{\text{ads}} = E_{\text{total}} - E_{\text{sub}} - E_{\text{mol}}$$

where  $E_{\text{total}}$  is the total energy of the  $\text{K}_2\text{S}_x$  adsorbed systems,  $E_{\text{sub}}$  and  $E_{\text{mol}}$  are the energies of the substrate and the isolated  $\text{K}_2\text{S}_x$  molecule, respectively.

#### 4.9. Potassium-ion full cell of $\text{Cu}_3\text{PS}_4/\text{G} // \text{K}_x\text{Fe}[\text{Fe}(\text{CN})_6] \cdot y \text{H}_2\text{O}$

The CR2032 potassium-ion coin type full cell was assembled by setting the cathode-to-anode overall mass ratio to be 5. Before full cell assembly, both anode and cathode were preactivated for 20 cycles and discharge to 0.01 V followed by constant voltage process to maintain the state of the electrodes. Then, 1 M KFSI in DMC was applied as electrolyte and the working window of the full cell was set between 1 V ~ 3.99 V.

#### 4.10. Potassium-ion hybrid capacitor of $\text{Cu}_3\text{PS}_4/\text{G} // \text{AC}$

The potassium-ion hybrid capacitor was assembled by using  $\text{Cu}_3\text{PS}_4/\text{G}$  for anode and active carbon for cathode, with an overall mass ratio to be 1. Before the hybrid capacitor assembly, the anode was preactivated for 10 cycles and discharge to 0.01 V. Afterwards, we used 1 M KFSI in DMC as the electrolyte and set the working window of the hybrid capacitor between 0.5 V ~ 3.99 V.

### Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

### Data availability

No data was used for the research described in the article.

### Acknowledgements

This work was supported by the financial support from the 2030 Cross-Generation Young Scholars Program by Ministry of Science and Technology, Taiwan (MOST 111-2628-E-007 -008). H.-Y. Tuan also acknowledges the financial support of National Tsing Hua University, Taiwan, through the grant of 111QI030E1.
